

the need for further review.

Upon receiving the assessment, Admiral Seguros uses it to make immediate payment offers to policyholders when appropriate, allowing them to resolve claims in minutes, even on the first call.

The developed AI solution uses deep learning for computer vision, in addition to machine learning (ML) techniques. It is trained with millions of photographs of vehicle damage, and the algorithms learn from experience by analysing a wide variety of different examples, allowing it to be implemented globally to any vehicle. The AI enables insurers to assess car damage, share recommended repair operations, and guide the claims management process to ensure these are processed and settled as quickly as possible.

This chip transforms every watch into a contactless payment device

The Swiss company Winwatch has integrated a tiny security chip from Infineon Technologies into its patented sapphire crystal STISS for enabling fast and secured payment transactions by radio frequency within milliseconds.

It is a mini-computer measuring just a few square millimetres that initiates and controls all communication between the customer and the financial institute via a small antenna.

Within around 200 milliseconds—the blink of a human

eye—the chip proves the authenticity of the device with an individual signature and creates a cryptogram of card data, payment amount, and place of payment. After successful verification, the bank confirms the payment to the reader.

Communication between the card or wearable and the reader is based on Near Field Communication (NFC) technology. At a distance of two to ten centimetres, the chip uses only the energy field of the reader to calculate, encrypt, and transmit the data.

New multirotor drones equipped with advanced hover-in-place technology

Dragonfly Pictures Inc. (DPI) has developed a new class of drone, the hover-in-place tethered drone. Unlike battery-powered multirotor drones that require battery changes every twenty minutes, tethered drones receive their power through

an electrical cord connected to a base station.

This enables them to stay aloft for hours, even days. DPI's tethered multi-rotor drones have been designed to track and follow mobile host platforms, including ships, boats, trucks, and other unmanned surface/ground vehicles.

These offer several benefits over fixed-wing drones, including vertical takeoff and landing capabilities, and no runway, launcher, or recovery equipment is required. Unlike a blimp, these have the ability to achieve continuous, stationary positioning—even during turbulent weather and fast-changing wind speeds.

DPI's military/industrial-grade Unmanned Multirotor Aerial Relay (UMAR) tethered drone is weatherproof for environmental conditions such as rain, snow, dust, and heat. It is also optimised specifically for saltwater marine environments.

UMAR drones are beneficial in that they can provide up to 400+ hours of non-stop uptime. But there are significant design challenges inherent to tethered architecture. The power needs to be delivered from the host vessel to the multirotor drone at extremely high voltage and low current to enable the use of the thinnest and lightest tether, which in turn enables greater drone mobility and larger airborne payloads.
